ABSTRACT

Optically Detected Magnetic Resonance; Computational Predictions and Experimental Results

Scott Leland Crossen

Department of Physics and Astronomy, BYU
Bachelor of Science

Electron Spin Resonance (ESR) is an important tool in understanding the quantum-mechanical properties of condensed matter. It's applications range from studying lattice-defect in solids to studying spin coherence in qubit candidate materials used for quantum computing. When coupled with a photoluminescence measuring component, a double-resonance-technique allows for optical readout of ESR information. This unique form of ESR is called *Optically Detected Magnetic Resonance* (ODMR). In this thesis we compare experimental ODMR data with ESR predictions generated from computational modelling systems. To investigate the differences between these two methods we will study one spin-system in particular: irradiated 4H silicon carbide. This specimens will serve as the primary means to connect experimentally and theoretically the two very different forms of computational and practical ESR spectroscopy commonly used today. Methods and theory for both methods will be described and resulting spectrums will be overlaid for comparison. Though there will always be some differences, results show that computational ESR predictions match experimental results to the same extent that the underlying Hamiltonian for that particular system is understood.

Chapter 1

Introduction

1.1 Qualitative Description of ESR and ODMR

Optically Detected Magnetic Resonance (ODMR) is a particular form of *Electron Paramagnetic Resonance* (EPR) which is more commonly known as *Electron Spin Resonance* (ESR). The latter two of these terms (EPR and ESR) are synonymous; The former (ODMR) is a particular subset of ESR that utilizes a luminescence measuring technique as a means to collect ESR information. In literature, it is common to see both of these terms followed by the designation “spectroscopy” which signifies that they are tools to study properties of matter via electromagnetic radiation. Though the extent of their application has grown over the years, ESR and ODMR are most commonly used to study the spin-properties of electrons and electron-holes trapped in metal lattices. They can be used to study free radicals (Kobayashi 2015) in organic materials and are also important in studying the local environment of lattice defects through a technique using angular-dependent ODMR. One particular use of ODMR is the study of electron-spin coherence via a technique known as *Electron Spin Echo*. This can be useful when studying what properties and conditions lead to superior state coherence (Bar-Gill et al. 2013) for qubit candidate materials in

quantum computing.

The intellectual foundation of Electron Spin Resonance is rooted in Quantum Mechanics. Bound electrons in matter have discrete and quantized energy levels that govern what frequencies of light are emitted when transitions between energy levels are made. For electron systems, which are fermions and thus subject to the Pauli exclusion principle, the energy levels are 2nd order degenerate when bound in matter. In Quantum Mechanics we choose to describe this degeneracy in terms of spins: we say an electron is either “spin-up” or “spin-down”. Each energy level can have at most two electrons of opposite spins inhabiting it (and thus the degeneracy). The spin terminology is arbitrary however, and is really just an attempt at comparing electrons to particles. In truth, electron spin is a term for a property that is emergent from solving the wave equation. However, it nonetheless describes the principle of conservation of momentum that would be found in classical system such as a top and so the term makes sense and has persisted in usage today. In this case, the electron’s spin is a description of the magnetic moment for when the particle is in the presence of a magnetic field. In the case of electrons bound in matter within a magnetic field, the energy levels of the molecule will split according to the “Zeeman Effect” and the spin-states of the electrons can be observed - most commonly through a photoluminescence or other fluorescence measuring technique.

The Zeeman effect itself is crucial in understanding the principles of ESR. In the presence of a magnetic field, populations of free electrons will form a spin-1/2 system between a higher-energy “spin-up” state and a lower-energy “spin-down” state. In matter, different parities of spin-states can be formed between the interactions of different energy levels with different transition selection rules. A spin-1/2 system in the presence of a magnetic field is shown in 1.1. As seen here, the energy levels of the two differing spins diverge linearly for an increasing magnetic field. The difference in energy between these two levels is typically in the microwave frequency domain. For a given magnetic-field strength there will be a set of characteristic microwave frequencies that

Figure 1.1 Zeeman effect for a two level system showing spin ($\pm 1/2$) energy levels as a function of applied magnetic field. For arbitrary field strength the energy difference is shown as a function of μ , g , and the field strength B .

the electrons are most prone to emitting when transitioning between these quantized states. In a spin-1/2 system there will only be one frequency for a given magnetic field corresponding to the difference between the two Zeeman lines at the given field strength. Likewise, for a given microwave target signal, there will be a variety of magnetic field strengths which are most adept at transitioning bound electrons between states. This unique pairing between both the microwave frequency and magnetic field strength is the resonant condition upon which ESR is based off of and also the means it uses to discover information about materials.

1.2 Electron Spin, Quantum Computing, and Qubits

Classical Computation is almost always based upon a binary system. In these architectures, the computer's register, memory, and general logical states are either in a logical 'true' or a logical 'false' state. A 'true' state corresponds to a high voltage and a 'false' state corresponds to a

grounded voltage. A computer's bits can be in either of these two states - 1 or 0 - but not both.

A spin-1/2 system also describes a binary system between a higher-energy basis state and a lower-energy basis state. In this comparison, the spin-1/2 system will be measured (and the wave function collapsed) to be in either of these two states - but not both. The important difference between the the spin-1/2 system and the classical computer bit model is that the spin system can have states that exist as linear combinations of the two basis up/down states. In accordance with Quantum Mechanics, this means that the spin-1/2 system can exist as a superposition between both the spin-up and spin-down states and has a certain probability of being measured in each. It is important to note that this superposition does not mean that the state exists as some value in between an excited state and a lower state. Rather, it exists with some value in both states simultaneously.

Because of this unique property of spin systems, they can be used as a basis for forming what is called a "quantum computer" (Bennett & Divincenzo 2000). Though it largely depends on the architecture, Quantum computers can be thought of to manipulate information in a similar fashion to that of a classical computer. Both have logical operators and storage bits and both are algorithmically based. Quantum computers, however, utilize this unique possibility of superposition to make probabilistic calculations for many different states at the same time. This happens through the quantum mechanical operators that initialize and manipulate the states that are stored in "qubits" - or the quantum computer's version of classical bits that can exist in these superposition types of states. Because of the existing theoretical construction from nondeterministic finite automata to deterministic finite automata, quantum computers are also "turing complete" in the broad definition of that term. This statement is trivial however, because quantum computers can be operated in the discrete binary limit and so should be able to do anything a classical computer can.

Today, there is large emphasis within the scientific community in building viable, scalable quantum computers. The reason for this is that quantum computers offer reduced computational

time limits for certain types of algorithms. Certainly however, these machines are not necessarily more adept at common tasks such as processing videos to be scrubbed by common users, but are rather designed to carry out a few types of intense calculations in logarithmic time that would normally have a polynomial time dependence. The most notable use for quantum computers in our modern society is within the field of computer security and encryption. Quantum computers have the ability to compute prime factors via Shor's algorithm in a much faster time than traditional computers (Shor 1999). This ability would essentially render all of the current RSA encryption methods obsolete in addition to anything that relies on public/private key encryption such as bitcoin.

Although more than just spin systems can be used as the all-important qubits for quantum computing, we will focus on this type - specifically spin-1/2 systems formed from electrons - for the basis of our discussion (Astakhov et al. 2016). As mentioned earlier, ESR is the major tool used to study the spin properties of materials. In the case of quantum computation, ESR is used to study possible qubit materials that might eventually be used in such machines. Currently, one of the major difficulties in creating quantum computers is finding materials that can form superposition states that remain coherent (and reliable) over prolonged periods of time. In order to understand what properties of materials lead to superior qubit construction and state coherence, ESR can be used in conjunction with electron spin echo experiments to study the coherence of electrons in a spin-1/2 system. Moreover, ESR can be used alone to study the spin system itself and the local environment of the defects in materials that form them. Knowledge of this important topic will serve to increase our ability to construct better qubits for use in quantum computers.

1.3 The Defect Nature of Materials

In solid-state physics, materials form crystal lattices for molecular tessellation. These structures are not perfect, however, and often have intrinsic interstitial defects (Stavola 1998). These defects come in the form of either additional or missing atoms. Crystal lattice defects as they are called are important as they contribute to the overall spin system of the material via either electrons or electron-holes (Carlos et al. 2006). For the case of some materials, these defects can be introduced via high-fluence irradiation of particles.

1.4 Previous Work (Our Research Group and Others)

1.4.1 Preliminary Work and Results

The work performed in this thesis references in large part the work done by Kyle Miller and Jacob Embley - two students who worked under Dr. John Colton and have since graduated from Brigham Young University. Their work was mostly performed on the topic of electron spin coherence in proton-irradiated silicon carbide and is documented in their senior theses both of related titles (Miller 2015) (Embley 2016). This thesis, however, will not be on the same topic as the former two but will expand on one aspect used by both of these two students in their work - ODMR. In addition, both Miller and Embley used a particular species of SiC which is one of the two principal materials of investigation in this thesis.

The reference section includes a publication that Embley, Colton, Miller, myself and a few others produced on the topic of spin coherence in proton irradiated silicon carbide (Embley et al. 2017). It has been accepted by *Physical Review B* and will appear in publication later in the year 2017. This publication serves as a capstone to the work of both Embley and Miller as included in their senior theses and will serve as the context for which this thesis was produced.

In addition to the work done by Miller and Embley, an additional study was performed on a similar material of the SiC specimen which is not included in either the aforementioned theses or publication. This project is included in Appendix A. The major difference with Appendix A and the theses produced by Miller and Embley is the fluence of irradiation used on the SiC sample in question. Miller's work was primarily concerned with a 10^{14} cm^{-2} proton-irradiated sample of SiC. Embley likewise worked with a 10^{13} cm^{-2} proton-irradiated sample of SiC. In Appendix A I work with a 10^{17} cm^{-2} electron-irradiated sample of SiC in much the same way as used by Embley. With this additional sample, a more comprehensive analysis and additional results are presented.

1.4.2 Experimental Setup

The experimental setup used for the majority of this thesis was set up and tested by Kyle Miller and Jacob Embley. Miller initially set up all the necessary instrumentation to be used in his experiment which is detailed in his thesis. Later, Embley improved upon most of Miller's design and achieved increased precision and improved results (Embley 2016). The experiment used by both Embley and Miller was eventually repurposed and slightly modified for the experiment detailed in this thesis. A full summary and implementation of the experimental setup can be found in 3.3. This section includes both the setup used by Miller and Embley as well as the components I modified for the purposes of performing this work.

1.4.3 Samples and Collaborative Efforts

The work done for this thesis was done in collaboration with two groups of people. Firstly, the silicon carbide samples used were produced and partially characterized by Dr. Sam Carter of the Naval Research Lab (Carter et al. 2015). These samples were irradiated with different fluences of particles in order to introduce different concentrations of defects into the material. It was Carter's

work that ultimately led us to obtain such high quality samples for optical characterization and Electron Spin Resonance studies.

1.4.4 Preliminary Results of Experimental ODMR

The work done for this thesis is based around one primary material. This material, SiC, has had prior work done on it for ODMR characterization.

Dr. Sam Carter of the Naval Research Lab provided the samples for the silicon carbide used. In addition, he also presented a series of plots to describe the spin system present in the material. According to the information he provided, the silicon vacancies in silicon carbide form a spin-3/2 system with a metastable doublet state to allow for non-radiative transitions. Another interesting characteristic of this system is that it has a zero-field splitting effect which accounts for a difference of energies without a magnetic field between the spin states $+1/2$ and $+3/2$ with $-1/2$ and $-3/2$.

In addition to the information provided by Dr. Carter regarding the spin system of SiC, he also provided preliminary ODMR results performed at low field strengths of around 31 mT (Carter et al. 2015). The results of his measurements are found in 1.3 and show the transitions between different spin states which will be more fully developed in 3.1.1. Moreover, Carter also provided angular dependent measurements of the resonant relationship between magnetic field strength and microwave frequency. As mentioned in 1.1, there exists a unique pairing between the applied magnetic field and the resonant microwave energy transition. For a given magnetic field there will exist different resonant frequencies depending on the spin system in question. In addition, these characteristic frequencies will have associated linewidths that describe what range of frequencies the gaussian distribution is centered around and how wide it is. For the case of a spin-3/2 system as found in 4H-SiC, the relationship is best represented by 2.4 which is a plot produced by Dr. Carter for the samples used in this project (Carter et al. 2015).

Figure 1.2 The relationship between magnetic field strength and microwave Frequency for 4H-SiC, a spin-3/2 system. Resonant conditions are shown via bright coloration on the axes of frequency vs field. Notice the linear dependence between both microwave energy and field strength.

Figure 1.3 The preliminary ODMR data for proton irradiated silicon carbide in a constant magnetic field of 28 mT. The plot shows resonant paramagnetic conditions at 718 MHz and 857 MHz where the absorption is greatest.

1.4.5 *EasySpin* Computational Modeling System

EasySpin (Stoll & Schweiger 2006) is a library for MATLAB designed to computationally model ESR data. The majority of computational work for this thesis was done using this program which was provided free of charge by the vendor's website. Though most of the necessary functions to model ESR data were included in the *EasySpin* library, I still found it necessary to create custom definitions in addition to what was already supplied.

1.5 Overview of Thesis

The purpose of this thesis is to describe in detail the methods and procedures behind experimental and theoretical ESR and to answer the question as to how both experimental and theoretical methods compare to each other. By so doing we will also introduce the fundamental theory behind ESR and computational modelling packages such as *EasySpin*. In addition, we will also discuss the experimental frameworks and setups necessary for collecting ODMR information from materials. This analysis will not be comprehensive but is rather purposed as an introduction into the techniques used in the field. As such, we will restrict our analysis to only solid-state ESR and ODMR.

We will use one main materials for this thesis: SiC. This material will be valuable in our understanding of lattice defect contribution towards ODMR results. In addition, we will primarily use this material as a control to compare the experimental data with respective computational predictions. It will be through this specimen that we will ultimately show the similarity between experimental results and theoretical predictions.

In the end, this thesis will conclude that computational modelling is accurate to the same degree as the spin system is understood. In other words: the level of precision that computational modeling can present is restricted by how much information is known about the Hamiltonian for that given

system.

1.6 Explanatory Notes and Background Information

The content of this thesis will use the term *ESR* when referring to the general theory and mathematical model of Electron Spin Resonance and will use the term *ODMR* when referring to the experimental methods used for collecting ESR information. As mentioned earlier, ODMR is a specific type of ESR that is ultimately used to collect the same information through a fluorescence technique. Because we have implemented an ODMR-type experiment in our lab we will use this term for descriptive accuracy when referring to our experimental application.

By way of information, the work done for this thesis was performed using MATLAB R2016b (version 9.1) and *EasySpin* version 5.1.9 . It will be assumed that the reader is proficient in basic MATLAB or C constructs and is at least familiar with data types and terms such as “struct”, “parameter” and “field” as related to computer programming.

All plots and figures were created using a combination of Mathematica version 10.4 and Origin version 7.5.

In addition, pertinent git repositories will be hosted online via GitHub for all code developed for this project. The LabVIEW suite used for data acquisition can be found at the permanent URL <https://github.com/coltonlab/LabVIEW-programs>. The programs developed on top of the *EasySpin* library that were used for theoretical modeling can be found along with this thesis at <https://github.com/scottcrossen/SeniorThesis>.

Chapter 2

Computational Model and Theory

2.1 Mathematical Theory

As mentioned in the Introduction, spin systems and Electron Spin Resonance (ESR) are best understood in terms of interaction Hamiltonians. ‘Hamiltonians’ in this context are quantum mechanical operators (as opposed to the classical mechanical version) that act on energy states and form specific eigensystems with defined energy eigenvalues. For example, in the Zeeman effect there exists a Hamiltonian that – when diagonalized – gives the energy-splitting for a given magnetic field in terms of its eigensystem. Since ESR spectroscopy measures the resonant conditions between energy-levels and magnetic field strength, it is important to find the field-dependent Hamiltonian for each system before we can calculate the theoretical ESR spectrum.

Thankfully, the general Hamiltonian for atoms in a magnetic field is commonly known (Pake 1973) (Poole 1994). In this case, the interaction energy of an atom in a constant magnetic field is given by the overall spin Hamiltonian \mathcal{H}_{tot} (Poole 1967)

$$\mathcal{H}_{\text{tot}} = \mathcal{H}_{\text{elect}} + \mathcal{H}_{\text{cf}} + \mathcal{H}_{\text{LS}} + \mathcal{H}_{\text{SS}} + \mathcal{H}_{\text{Zee}} + \mathcal{H}_{\text{hfs}} + \mathcal{H}_{\text{Q}} + \mathcal{H}_{\text{N}}$$

where $\mathcal{H}_{\text{elect}}$ is the electronic energy, \mathcal{H}_{cf} is the crystal field energy, $\mathcal{H}_{\text{LS}} = \lambda \mathbf{L} \cdot \mathbf{S}$ is the spin-

orbit interaction, $\mathcal{H}_{\text{ss}} = D \left[S_z^2 - \frac{1}{3}S(S+1) \right]$ is the spin-spin interaction, $\mathcal{H}_{\text{Zee}} = \beta H \cdot (L + 2S)$ is the Zeeman interaction energy, $\mathcal{H}_{\text{hfs}} = (A_x S_x I_x + A_y S_y I_y + A_z S_z I_z)$ is the hyperfine structure, \mathcal{H}_{Q} is the quadrupole energy, and $\mathcal{H}_{\text{N}} = \gamma \beta_N H \cdot I$ is the nuclear spin energy. All of these components are defined in terms of the spin angular momentum operator S , the orbital angular momentum operator L , the Nuclear Spin Operator I , the Bohr magneton β , the spin-orbit coupling constant λ , the hyperfine coupling constant A , the nuclear gyromagnetic ratio γ , and the zero-field splitting constant D .

Some terms in the Hamiltonian dominate the system and can be focused on individually. Though we will not restrict our analysis solely to them, the most important term is the Zeeman interaction energy. For the high-field limit that we will be working with, the Zeeman interaction dominates all other perturbations. This effects the system by splitting energy levels linearly with increasing magnetic field. Though there are a few other constants involved in the calculation of the Zeeman Hamiltonian, the main parameter it requires is the all-important g-tensor. This factor simplifies to a factor for symmetric lattice conditions and it relates the spreading of the differing spin energy levels to the magnetic field. It is ultimately through this Zeeman effect that we are able to see resonant conditions between magnetic field strength and microwave frequency.

Once the Hamiltonian is known for the system, the ESR spectrum can be computationally predicted. A variety of methods are available to go from the basic Hamiltonian components to the finished ESR plot. The most notable is a software suite called *EasySpin* (Stoll & Britt 2009), which vastly simplifies the amount of calculations and explicit Hamiltonian definitions that the investigator has to make.

2.2 *EasySpin* Interaction Modeling System

The purpose of this thesis is to comprehensively show the intricacies and unique methodologies of both computational and experimental ESR. As for the former of these two, the most common tool used to computationally model ESR is known as *EasySpin* (Stoll & Britt 2009). This package is built as an open library on top of the MATLAB program and serves to add functionality to the already-useful suite of functions that components within MATLAB.

2.2.1 The *EasySpin* Struct Definition

The core utility of the *EasySpin* package is the struct definition used in the spin system. The *EasySpin* library is built around the idea of a struct (a term describing a publicly-scoped group of fields) to define all necessary components of the system being studied. In fact, most methods in the *EasySpin* library usually require just a struct of this type as the sole parameter in the function declaration.

The struct represents the spin system and is usually defined by the user to the extent that the system is known. Though there are many optional parameters that can be included in the struct, the most simplest spin system needs to include a ‘.S’ parameter representing either a list or a value for the parity of spin being worked with as well as a ‘.g’ parameter to represent the g-factor of that material in solid-state ESR. The g-factor could be either a list or a value depending on the crystal type being investigated. After these two parameters are defined, the system can then be passed to any other functions for analysis and plotting. Figure 2.1 shows an example of what this basic definition might look like in MATLAB.

```

Sys.S = 1/2;
Sys.g = 2.017;
Sys.lw = 1;

Exp.mwFreq = 9.2; % GHz
Exp.Range = [320 330]; % mT

```

Figure 2.1 An example declaration of the basic *EasySpin* struct used in defining the spin system. In this example, ‘Sys’ represents an arbitrary name for the struct, ‘S’ is the spin parity, ‘g’ is the g-factor, ‘lw’ is the ESR line-width, ‘mwFreq’ is the position of the microwave frequency being probed, and ‘Range’ is the range of the magnetic field being scanned.

2.2.2 Basic Class Structure

The term ‘class’ is used loosely in this context. Unlike most languages, MATLAB (and thus *EasySpin*) is based on plain C and thus not really object oriented. However, unlike C, basic class definitions have been added to MATLAB though they aren’t commonly used. *EasySpin* uses a series of ‘.m’ files that represent different abstractions of the overall modeling system that may or may not be implemented in the form of classes. For this thesis, I will use the term ‘class’ to refer to any modular component of the provided *EasySpin* library.

The most notable classes that are supplied with the library are the core plotting functions for ESR spectrums. These include such jocose names as “garlic” for cw isotropic ESR and “pepper” (Stoll 2015) for solid state CW ESR (which I will use). Table 2.1 shows the full list of possible plotting functions supplied in the library. Other functions supplied in *Easyspin* are mostly related to data import/export, data analysis, and system optimizations.

In addition to the classes supplied in the *EasySpin* library, I have also built a few of my own for better visualization of spin systems. One such class (which is included in the online repository cited in the introduction) is called “zeeman.m”. This program draws the field splitting of the Zeeman interactions in the spin system over increasing magnetic field. Another class I implemented builds upon this one and is called “animate.m”. This draws the Zeeman diagram and then animates the

Table 2.1 List of possible *EasySpin* plotting functions. ‘*pepper*’ is the main function that will be used in this thesis.

Function	Description
garlic	cw EPR, isotropic and fast motion
chili	cw EPR, slow motion
pepper	cw EPR, solid state
salt	ENDOR, solid state
saffron	pulse EPR/ENDOR, solid state
curry	SQUID magnetometry
blochsteady	Bloch equations, steady-state
pulse	Shaped pulses
esfit	least-squares fitting

plot by drawing the resonant magnetic field differences for a given microwave frequency. Again, all of these additional classes are included in an online repository linked to in the introduction of this thesis.

2.3 Selecting Hamiltonian Arguments

In addition to experimentally gathering the ESR data via ODMR, this thesis is also concerned with emulating the ESR spectrum via EasySpin. However, in order to do this, the Hamiltonian for each material needs to be understood to the fullest possible extent.

Table 2.2 Summary of the spin-Hamiltonian parameters for the various defect centers of ZnO nanowires given by J. E. Stehr et al (Stehr et al. 2013). The spin-parity and diagonalized g-tensor values are given for each defect center. For the non-axial centers, φ is the angle between the z and c axis.

Center	S	Axial		Nonaxial			φ (deg)
		g_{\perp}	g_{\parallel}	g_{xx}	g_{yy}	g_{zz}	
V_{Zn}^-	1/2	2.0193	2.0024	2.0173	2.0183	2.0028	110.75
Z	1/2	2.006	2.020				20
V_{Zn}/Zn_i	1			1.9888	1.9893	1.9815	110.75
Zn_i^+	1/2	1.9595	1.9605				0
D^*	1/2	1.9595	1.9605				0

2.3.1 ZnO Nanowires

One of the works cited in this thesis investigates the resonant properties of zinc oxide nanowires (Stehr et al. 2013). The author, Stehr, models the ESR spectrum using g-tensor and spin-values given for each defect center. This data is summarized in table 2.2. Stehr uses the *EasySpin* modeling system to show the predicted ESR spectrum resulting from the V_{Zn}^- , V_{Zn}/Zn_i , and D^* defect center contributions. He models each Hamiltonian separately using *EasySpin* and then combines the results with MATLAB. Figure 2.2 shows the plots that he presented to the journal after this process.

However, one thing Stehr did not include was the ESR line-width parameters and derivations he used when constructing the spin system via *EasySpin*. As a verification for the process he used, I have included a reconstruction of the same ESR spectrum that was included in his publication. Through comparison I found that the line-width parameters used by Stehr were 1, 5, and 2 mT for V_{Zn}^- , V_{Zn}/Zn_i , and D^* respectively. Though it is unknown as to how he arrived at these values, it is likely that he compared the theoretical model to the experimental data until a reasonable fit was

Figure 2.2 The ESR spectrum presented by Stehr et al (Stehr et al. 2013). for ZnO Nanowires. The results of computational modeling using *EasySpin* are shown in dashed-red (individual) and solid-red (total). The black line represents actual data from the sample and the blue line is included for comparison to the bulk species.

Figure 2.3 The recreation of the plots given by Stehr et al. for the ZnO nanowire ESR spectrum. All three defect centers are included as in the original figure.

achieved. In Figure 2.3 I give the recreation of the spectrum and the code used to generate the spin system that Stehr used (Stehr et al. 2013).

Figure 2.4 A diagram showing the energy-levels of the spin-3/2 system inherent in 4H-SiC for the high-field limit. Allowed transitions are shown with solid colored arrows. Disallowed transitions are shown with dashed arrows

2.3.2 Irradiated 4H-SiC

One of the two primary materials studied in this thesis is silicon carbide. In order to compare the theoretical prediction of the ESR spectrum with experimental results we first need to discover what arguments are used in the overall spin Hamiltonian. Below I have listed the significance and value of each term used in the spin Hamiltonian. I have also included the pertinent code to represent this system in terms of the aforementioned *EasySpin* struct definition in figure 2.5.

SiC is a commonly known to be a spin-3/2 system with two major ESR peaks in its spectrum (Carter et al. 2015). The parameter ‘S’ given for the *EasySpin* system is then just 3/2. Moreover, as mentioned previously, SiC has one major defect of interest: the silicon divacancy (Srman et al. 2000) (Baranov et al. 2011) in its lattice structure. The g-factor for this defect center is given as a rhomboidal two-termed g-factor [$g_{xx} = g_{yy}, g_{zz}$] of almost eacatly 2 (Carter et al. 2015). This is listed as the ‘g’ parameter in the struct definition.

The linewidths are relatively narrow for specimens related to SiC. By comparison to experiment we have found that the full-width-half-maximum value of the line-widths is close to unity. Using *EasySpin* this means that the ‘lw’ parameter should be set to around 1

```

Sys.S = 3/2;
Sys.g = 2.008;
%Sys.A = ??;
%Sys.Nucs = '29Si';
Sys.D = 34;
Sys.lwpp = [8 1];
Sys.DStrain=5;

Exp.Field = 370.78; % mT
Exp.mwRange=[10.2 10.6]; % GHz
Exp.nPoints=1024;
Exp.Harmonic=0;
Exp.Temperature=298;
Exp.CrystalOrientation = [0 0 0]*pi/180;

Opt.Transitions=[1 2; 3 4];

```

Figure 2.5 The representation of the known parameters included in the *EasySpin* struct definition for analysis of 4H-SiC

One interesting property of this material is that it exhibits a zero-field splitting which divides the $+3/2$ and $+1/2$ from the $-1/2$ and $-3/2$ states even when there is no external magnetic field. In our definition we have measured this parameter to be about ‘.D= 70’ MHz at the zero-field marking (Carter et al. 2015). Moreover, only certain transitions are allowed in the SiC spin-3/2 system. Though other transitions can happen, they are unlikely and also undetectable because of the mechanism used by ODMR. For SiC the allowed transitions are between the energy levels of $+3/2$ to $+1/2$ and $-3/2$ to $-1/2$ (Carter et al. 2015).

Though it is not readily apparent, SiC also exhibits hyperfine splitting in its major ESR peaks. To observe this splitting, two terms can be added to the spin-system: ‘.A’ and ‘.Nucs’. For SiC these two parameters take on the value of ‘-120’ and ‘29Si’ respectively. However, in our example they are insignificant and therefore not included. In Figure 2.5 I have commented out these two lines of code to reflect that.

Chapter 3

Experimental Methods

The work done for this thesis uses both computational and experimental components in describing ESR. Whereas we described the process of theoretical/computational ESR in the last chapter, we will now describe the experimental-limit of this technique which we call ODMR due to its optical-coupling of information gathering. This chapter is primarily concerned with detailing the experimental methods implemented in typical ODMR setups. We will also first begin with a qualitative description of the material we studied (SiC).

3.1 Sample Preparation

3.1.1 Preparation of Silicon Carbide Samples

Three different samples of 4H-SiC were provided to us by our collaborator Dr. Sam Carter of the Naval Research lab. Each sample was prepared with a different irradiation fluence to introduce silicon defects into the lattice. The first sample that we tested was irradiated with 2 MeV protons at a fluence of 10^{14} cm^{-2} . The second sample was similarly irradiated with 2 MeV protons but at a fluence of 10^{13} cm^{-2} . The final sample was an electron-irradiated sample produced with a

Figure 3.1 Depth-dependent photoluminescence of the 10^{12} cm^{-2} sample at at major PL peak. The large peak at $34 \mu\text{m}$ indicates the stopping position of the protons. The spatial resolution was $1 \mu\text{m}$.

fluence of 10^{17} cm^{-2} . The different strengths of irradiation in each sample is presumed to change the concentration of vacancy defects formed within the sample.

A higher irradiation fluence typically produces a higher concentration of defects. Figure 3.1 shows the distribution of defects in a 10^{12} cm^{-2} sample as a function of spatial depth from the sample's normal face. This data was provided to us by Dr. Sam Carter as part of a "Stopping and Range of Ions in Matter" (SRIM) study to predict the stopping range for the protons inside this particular species of silicon carbide material (Carter et al. 2015). From the SRIM calculations, Dr. Carter predicted that the stopping distance of the ions would be at about $44 \mu\text{m}$ from the sample's surface. However, further photoluminescence studies showed the concentrations to be closer to about $32 \mu\text{m}$ rather than $44 \mu\text{m}$. Finally, each sample was cut such that the c-axis of the lattice was eight degrees from the direction normal to the sample face.

Figure 3.2 Photoluminescence plot showing PL strength vs. wavelength in SiC. The peak near 915 nm is the primary peak of interest as it represents the V2 silicon vacancy defect.

3.1.2 Photoluminescence Data

As mentioned earlier, ODMR is a particular type of ESR. The major difference is that ODMR uses a double-resonance technique to collect ESR data. Because of this, samples had to exhibit adequate resonance in their photoluminescence in order for the absorption of the microwave frequencies to be measured by our detectors. Figure 3.2 shows the photoluminescence spectra of SiC with the pertinent peaks of interest highlighted.

3.2 Experiment Background

The experiments performed in this thesis were performed in tandem with another study involving electron spin coherence in silicon carbide. The majority of the equipment used in the spin-studies project was used directly for collecting data for this thesis as well. Because of this, section 3.3 only summarizes the more important elements and details only those aspects of the experiment that significantly deviate from previous projects. For a more detailed description of the experiment

Figure 3.3 The diagram showing the necessary (labeled) components and arrangement for the ODMR experiment. A full description of each element is included in section 3.3.

please reference Jacob Embley's undergraduate senior thesis. (Embley 2016)

3.3 Experiment Setup

The overall setup used in this experiment is shown in Figure 3.3. The basic components necessary to collect ODMR data are: A laser to stimulate photoluminescence, a constant magnetic field, and an adjustable microwave generator to transition spins between energy levels. Though a cryostat was used, it was not needed and was included as just an artifact for previous experiments that used this same setup. For our purposes the cryostat kept the sample at a constant room-temperature for consistency in the experiment. These components are described in detail in the next section.

3.3.1 Temperature Controller and Static Magnetic Field

All samples studied were held at constant temperature and magnetic field. A nonmagnetic *CryoIndustries* cryostat was used to maintain constant temperature on the sample throughout the duration of the experiments. A turbopump was used in conjunction with the cryostat to keep the pressure around 10^{-5} mbar. A PID *CryoCon* controller was used as the heating element in the chamber.

When used in combination with the cryostat, any temperature between 8 K and 300 K could be achieved. Many different temperatures of ODMR were recorded for the samples between these two temperatures.

Most ESR-type experiments hold microwave frequency constant and sweep magnetic field strength, but for our purposes it was easier to do this in the reverse manner. As our data shows, the results can be interpreted the same way for either method. An external static magnetic field of 0.37 T was applied constantly throughout the experiment. A large iron-core electromagnet was powered using a Magna-Power Electronics TS Series IV power supply. A Lakeshore DSP 750 gaussmeter was used as a PID controller to make fine adjustments to the magnetic field so that it stayed constant at 0.37 T.

3.3.2 Laser and Optics

In order for photoluminescence to be measured off the sample, a laser must first stimulate the sample. The laser used for this experiment was a 3900 S Ti:Sapph laser tuned to 870 nm and pumped by a 532 nm solid diode laser. The Ti:Sapph was focused to around 50 micrometers and controlled by a Brockton Electro-Optics Corp BEOC laser power controller. The laser was chopped with a NEOS Technology 15210 acousto-optic modulator (AOM) and paired with a Stanford Research System lock-in amplifier recording filtered light from a photodiode.

3.3.3 Microwave Generation and Amplification

Microwaves induce transitions between the Zeeman energy levels and are the fundamental variable modulated to retrieve ODMR data. The microwaves used for this experiment were produced using an Agilent Technologies E8257D microwave generator set at 10.4855 GHz at 0 dBm. A 20T4G18 traveling wave tube microwave amplifier increased the power of the microwaves up to about 40 dBm. The microwaves were then fed to a coupling loop placed next to the sample within

the cryostat.

3.3.4 Software Controller Interfaces and Data Recording

All experiments were conducted using a LabVIEW suite of programs designed to succinctly gather and record ODMR data. For our experiment, the LabVIEW suite controlled the microwave and laser modulating so that both could be referenced with a lock-in amplifier as necessary. The microwave generator and lock-in amplifier were interfaced using a GPIB addressing bus implemented as a separate class instantiation in the main LabVIEW program. The instrument classes were all designed to run in parallel to the main scanning software for better experiment control. The generic scanner object was built to handle an abstracted object implementing a “scannable” interface and another object implementing a “readable” interface. The scanner was built robustly enough to handle any combination of instrumentation that inherits from these two interfaces. It gives directives to the “scannable” object while also recording data from the “readable” object at the same time. A beta version of the program is linked-to in the introduction of this thesis and represents the ongoing work of myself, Ryan Peterson, Kyle Miller, Phil White, John Colton, and others.

In addition to the main LabVIEW suite of programs used, an additional PID-controller VI was built to run on its own thread. This was used to handle the magnetic field strength incident on our sample and make minor adjustments to the power-supply for the magnet according to measurements read off of the gaussmeter inserted into the field.

The overall program accepts as input a range of microwave frequencies and then records the absorption from the sample representing the ODMR. After this data was recorded, a graphing software known as *Origin* was used to produce plots from the raw data. No other data analysis was needed apart from the straight reproduction of the raw data into readable plots. The concluding chapter shows these results.

Chapter 4

Results

This chapter presents the ESR spectrum of SiC for both computational and experimental methods. The results of these two methods are then compared and contrasted and their strengths analyzed.

4.1 Computational Predictions

Using computational methods via spin-Hamiltonian analysis with *EasySpin* we were able to recover the characteristic ESR spectrum shown in figure 4.1. The figure shows resonant conditions at something for a field strength of Something. Though there are only two major peaks, if we had defined our Hamiltonian further we may have been able to see smaller perturbation effects such as the fine and hyperfine structures.

4.2 Experimental Results

We successfully collected data showing the ODMR spectra for SiC. This data is shown in figure 4.2. The same trend is seen in this data as is shown in the previous predictions. Namely, there are resonant peaks at something for a field strength of something. Also apparent in this figure is

Figure 4.1 The uncorrected computational model for the ESR spectrum of 4H-SiC plotted for a magnetic field strength of $B=370.78$ mT. The plot shows the relation between microwave frequency absorption for a static magnetic field strength.

a minor splitting of each peak visible at the very top of each spectral line. This is attributed to higher-order structures resulting from the perturbation of the material's levels.

4.3 Data Analysis

The main expectation of the two different ESR methods is that they will produce spectral peaks at the same resonant microwave/magnetic field pairings. Moreover, it is also expected that the relative heights of each peak is the same when compared between plots. The data presented in the previous sections corroborate this condition. However, there is still some differences between the two different methods. For one thing, the experimental ODMR shows a higher noise-floor than the computational method. It's easier to predict cleaner spectrums when the only uncertainty is that of machine precision and not environmental effects.

Moreover, It is expected (and actually acceptable) that there will be some variations in the

Figure 4.2 The experimental ODMR results for 4H-SiC for a magnetic field strength of $B=370.78$ mT. Like the computational predictions, this plot also shows the relation between microwave frequency absorption for a static magnetic field strength.

results obtained between the two methods used to recover ESR information from materials. The most notable difference between the two methods is seen in the width of each spectral peak within the plots. This congruence is best explained using time-dependent perturbation theory in quantum mechanics. Theoretically the probability of transition between microwave-levels in the samples should reach a delta-function limit centered at the resonant frequency for that given field strength. However, this only holds for an infinitely-lasting excitation transition. In practice this condition is not feasible and ESR peaks are instead shown to have finite widths in the magnetic-field domain. The width of these peaks is largely determined by how long the transitioning microwave intensity is incident on the sample. In our experiment we used a lock-in amplifier that referenced a modulated microwave intensity that was chopped at 1 kHz. Though the experimental results are easily reproducible given the same component time and power, different investigations may find different values of width depending on what parameters the researchers use. It therefore is not hard

to explain why the computational predictions that were obtained for ESR do not always match the experimental results when there is such discrepancy among experimental procedures themselves. For our purposes a spectral line-width was used to best match the experimental results that we obtained. The computational spectral widths should therefore match fairly close to the experimental results.

One of the major problems with modeling ESR spectrums is that so many minor experimental conditions can fundamentally change the spin-system being studied and thus change what the resultant spectrum looks like when being modeled. As mentioned, computational models are only effective to the extent that the Hamiltonian for the system is understood. For the case of silicon carbide there is still many details about the material that are not well understood – or simply not known – about the system. For example, there is still a lot of speculation and ignorance regarding the exact effect of the nuclear-spin interaction as well as the effects of the ODMR PL-mechanism, and the effects of the inhomegenous distribution of defects in the sample. To account for this, figure 4.3 shows the data from figure 4.1 except with the spectral peaks treated separately in the Hamiltonian such that the relative peak-heights can be adjusted appropriately to match the experimental results.

4.4 Conclusion

The primary conclusion of this thesis regards the equivalency between computational and experimental ESR. Though there are some differences between the two methods, the results show that computational ESR predictions match experimental results to the same extent that the underlying Hamiltonian for that particular system is understood. In other words: the level of precision that computational modelling can present is restricted by how much information is known about the Hamiltonian for that given system. Furthermore, there will always be some ambiguity between

Figure 4.3 The manually-corrected computational model for the ESR spectrum of 4H-SiC plotted for a magnetic field strength of $B=370.78$ mT. In this plot the first minor peak has been corrected to reflect the unknown effects resulting from differing populations of spins inherent in the sample, the selection-effects of the ODMR mechanism, as well as minor nuclear-spin interactions.

ODMR results and predictions due to practical considerations such as noise and ESR line-widths. Overall however, computational methods are good approximations of actual ESR results.
